ABSTRACT
Within a fully cosmological hydrodynamical simulation, we form a galaxy which rotates at 140 km s\(^{-1}\), and it is characterized by two loose spiral arms and a bar, indicative of a Hubble-type SBc/d galaxy. We show that our simulated galaxy has no classical bulge, with a pure disc profile at \(z = 1\), well after the major merging activity has ended. A long-lived bar subsequently forms, resulting in the formation of a secularly formed ‘pseudo-’ bulge, with the final bulge-to-total light ratio of 0.21. We show that the majority of gas which loses angular momentum and falls to the central region of the galaxy during the merging epoch is blown back into the hot halo, with much of it returning later to form stars in the disc. We propose that this mechanism of redistribution of angular momentum via a galactic fountain, when coupled with the results from our previous study which showed why gas outflows are biased to have low angular momentum, can solve the angular momentum/bulgeless disc problem of the cold dark matter paradigm.

Key words: galaxies: bulges – galaxies: evolution – galaxies: formation – galaxies: spiral.

1 INTRODUCTION

The cold dark matter paradigm successfully explains many properties of large-scale structure observed in the Universe (Blumenthal et al. 1984). On galactic scales, however, some problems exist which cast doubt on the properties of dark matter, and the assumption that it is non-relativistic (cold), not the least of which is the ‘angular momentum problem’.

The angular momentum of disc galaxies is imparted by torques from large-scale structure on dark matter and gas at the time at which they begin to collapse under gravity (Peebles 1969; Barnes & Efstathiou 1987). Disc galaxies will form, under the assumption that the angular momentum of the gas is conserved as it cools to the centre of the dark matter halo in which it resides (Fall & Efstathiou 1980; White 1984). Problems with this picture of disc galaxy angular momentum acquisition were highlighted in hydrodynamical cosmological simulations, which showed that when gas cools to the centre of dark matter haloes and forms stars, subsequent merging of the resultant proto-galaxies results in the catastrophic loss of angular momentum (Navarro & White 1994). This resulted in galaxies dominated by spheroidal components which were deficient in angular momentum when compared to their observed counterparts (Navarro & Steinmetz 2000). A closely related issue is that bulges form during mergers, as gas loses angular momentum and rapidly cools to form stars in the centre of the galaxy (Barnes & Hernquist 1996). These aspects of the angular momentum problem have significantly improved with better modelling and resolution of feedback processes, thus preventing stars from rapidly forming in the central regions of the early collapsing dark matter haloes (Thacker & Couchman 2001; Brook et al. 2004; Governato et al. 2007). This is reflected in recent simulations showing improved matches to the Tully–Fisher relation (Governato et al. 2007; Agertz, Teyssier & Moore 2011; Guedes et al. 2011; see also Section 3 in this paper).

Another manifestation of the problem is that the angular momentum distribution of simulated dark matter haloes differs markedly from that of observed galaxies. This is in conflict with the assumption that the distribution of the angular momentum of gas and dark matter is the same, an assumption which holds in non-radiative hydrodynamical simulations (van den Bosch et al. 2002; Sharma & Steinmetz 2005). In particular, dark matter haloes have a significant amount of low angular momentum material (Bullock et al. 2001), and in models of galaxy formation the corresponding low angular momentum baryons are expected to form a bulge component (van den Bosch 2001).

In contrast, many observed disc galaxies do not have bulge components (e.g. Allen et al. 2006; Cameron et al. 2009; Kautsch 2009).
and have angular momentum distributions that lack the significant amount of low angular momentum that is found in dark matter haloes (van den Bosch, Burkert & Swaters 2001). The situation is worsened considerably when one considers that many bulges have characteristics that indicate that they were formed secularly by processes within the disc itself, rather than being related to merging or cold dark matter structure formation (Kormendy et al. 2004; Kormendy et al. 2010).

The most recent simulations of massive disc galaxies continue to form classical bulges [bulge-to-total light ratio (B/T) = 0.19 in Agertz et al. (2011) and B/T = 0.25 in Guedes et al. (2011); see also Scannapieco et al. (2010); Stinson et al. (2010); Brooks et al. (2011)]. We note that Guedes et al. (2011) claim that their bulge is secular in nature, based on the low Sérsic index of the bulge in their two-component bulge-disc decomposition. However, they also state that their B/T has doubled since z = 3, indicating that their bulge is at least partially classical. These latest simulations have nevertheless formed significantly improved realizations of Ld galaxies. Yet the angular momentum problem, and the associated problem of forming disc galaxies which do not have classical bulges, remains a serious challenge for the cold dark matter paradigm.

Assuming the verity of the cold dark matter paradigm, it would seem that the resolution of the angular momentum problem requires either the ejection or redistribution of low angular momentum material. Ejection of low angular momentum material has certainly been proposed (Binney, Gerhard & Silk 2001; Maller & Dekel 2002; Dutton & van den Bosch 2009). Indeed, the ejection of low angular momentum gas by supernova explosions was shown to be key to the success of the first simulated bulgeless dwarf galaxies, which share many characteristics with observed dwarf galaxies (Governato et al. 2010; Oh et al. 2011). The processes which result in the ejection of low angular momentum gas from low-mass galaxies, and the key role this has in suppressing bulge formation, were outlined in Brook et al. (2011, Paper I).

The large-scale ejection of low angular momentum gas meshes well with the need to enrich the intergalactic medium (IGM; Mac Low & Ferrara 1999; Oppenheimer & Davé 2006; Shen, Wadsley & Stinson 2010), and also with the observed low baryonic mass fraction of low-mass galaxies (e.g. Klypin et al. 1999; Mandelbaum et al. 2006; Koposov et al. 2008; Guo et al. 2010; Moster et al. 2010). However, in the absence of active galactic nucleus (AGN) feedback, more massive galaxies with larger potential wells will have greater difficulty ejecting their gas. This is reflected in the strength of the relationship between total mass and the baryonic mass fraction; higher mass disc galaxies have significantly higher baryonic mass fractions, retaining a far larger proportion of the cosmic baryon fraction. This means that the large-scale outflow of low angular momentum gas is not likely to explain the fact that many massive disc galaxies do not have classical bulges (Kormendy et al. 2010).

Thus, processes which redistribute low angular momentum material may be necessary in higher mass disc galaxies. In this paper, we propose that galactic fountains are an effective mechanism for such redistribution. It is generally accepted that supernova-powered bubbles drive gas out of the galactic disc and through the halo. The expelled gas eventually falls back on to the disc, a mechanism known as a galactic fountain (Shapiro & Field 1976; Bregman 1980). Here, we examine galactic fountains on larger scales, both spatially and temporally, by examining the fate of gas expelled from the inner regions of galaxies as they are assembling their mass at high redshift. It is well established that supernova-driven winds can result in gas outflows (Mathews & Baker 1971; Veilleux, Cecil & Bland-Hawthorn 2005) and that starbursts trigger strong outflows from the central regions, particularly during merger events (Chevalier & Clegg 1985; Heckman, Armus & Miley 1990; Strickland & Heckman 2007; Tremonti, Moustakas & Diamond-Stanic 2007). Outflows are expected, and indeed observed to be more common at high redshift where star formation is more active and potential wells shallower (Madau et al. 1996; Pettini et al. 1998, 2000; Simcoe, Sargent & Rauch 2002; Shapley et al. 2003; Adelberger et al. 2005). The bipolar structure at the Galactic Centre (Bland-Hawthorn & Cohen 2003; Su, Slatyer & Finkbeiner 2010) lends support to galactic scale outflows from the central regions, even locally. The fate of such outflowing gas is not well constrained. As explained above, there is reason to believe that large amount of the gas will be lost from low-mass galaxies, but it is likely that some or even most of the outflowing gas will cool back to the star-forming region of higher mass galaxies.

Our model is based on analysis of our fully hydrodynamical cosmological galaxy formation simulations. Our simulation programme is running disc galaxies which span four orders of magnitude in stellar mass, from dwarf to Ld, all using the same resolution and input physics. We note that this input physics is similar to that which simulated the first bulgeless dwarf galaxies (Governato et al. 2010), and that we reproduce all the features of those successful simulations in our dwarfs. The simulation presented here also has input physics and resolution similar to the recent simulation of Guedes et al. (2011), which formed a much improved realization of an Ld galaxy. Here we examine a simulated disc galaxy in an intermediate-mass range, where the majority of observed isolated galaxies are dominated by their disc components.

This paper proceeds by providing details of the simulation (Section 2), and then describes the properties of the simulated galaxy (Section 3), and in particular it show that the simulated galaxy has no classical bulge. In Section 4, we identify gas which is blown from the bulge region and returns via the galactic fountain to form stars at later times and show that this re-accreted gas has gained angular momentum before it forms stars. In Section 5, we discuss our modelling of feedback from supernovae and its effect on the interstellar medium (ISM), central energy sources and angular momentum transport. We conclude (Section 6) that galactic fountains are effective in redistributing the angular momentum of gas and propose that this mechanism plays a crucial role in reconciling observed massive disc galaxies which do not have classical bulges with the A cold dark matter paradigm.

2 THE SIMULATION

The simulation described here is a cosmological zoom simulation derived from the McMaster Unbiased Galaxy Simulations (MUGS). See Stinson et al. (2010) for a complete description of how those galaxies were selected and their initial conditions were created. Here, those initial conditions are scaled down, so that rather than residing in a 68 h⁻¹ Mpc cube, it is inside a cube with 34 h⁻¹ Mpc sides. This resizing allows us to compare galaxies with exactly the same merger histories at a variety of masses. We selected a MUGs galaxy (15784) which had a prominent disc component for this study. The virial mass of the simulated galaxy in this study is $M_{vir} = 19.4 \times 10^{10} M_{\odot}$.

The simulation is evolved with the smoothed particle hydrodynamics (SPH) code GASOLINE (Wadsley, Stadel & Quinn 2004). GASOLINE employs cooling due to H, He and a variety of metal lines, and is described in detail in Shen et al. (2010). The metal cooling grid is constructed using CLOUDY (version 07.02; Ferland et al. 2011, Paper I).
et al. 1998), assuming ionization equilibrium. A uniform ultraviolet ionizing background (Haardt & Madau 1996) is used in order to calculate the metal cooling rates self-consistently.

Two mechanisms are used to prevent gas from collapsing to higher densities than SPH can physically resolve: (i) to ensure that gas resolves the Jeans mass and does not artificially fragment, pressure is added to the gas according to Robertson & Kravtsov (2008), and (ii) a maximum density limit is imposed by setting a minimum SPH smoothing length of 0.25 times that of the gravitational softening length of $\epsilon = 155$ pc. We have $\sim 9$ million resolution elements ($1.1 \times 10^6$ gas $+ 5.3 \times 10^6$ dark matter $+ 2.3 \times 10^6$ star) within the virial radius at $z = 0$, with mean stellar particle mass of $\sim 6400 \, M_\odot$.

2.1 Star formation and feedback

When gas reaches cool temperatures ($T < 15\, 000 \, K$) in a dense environment ($n_\text{th} > 9.3 \, \text{cm}^{-3}$), it becomes eligible to form stars. This value for $n_\text{th}$ is the maximum density gas can reach using gravity, $32 M_\text{gas}/\epsilon^3$. Such gas is converted into stars according to the equation

$$\Delta M_\star \Delta t = c_\text{s} M_\text{gas}/ \epsilon \text{dyn}.$$  \hspace{1cm} (1)

Here, $\Delta M_\star$ is the mass of the star particle formed; $\Delta t$ is the time-step between star formation events, 0.8 Myr in these simulations; $M_\text{gas}$ is the mass of the gas particle and $\epsilon \text{dyn}$ is the gas particle’s dynamical time. Note that $c_\text{s}$ is the efficiency of star formation; in other words, the fraction of gas that will be converted into stars during $\epsilon \text{dyn}$.

Stars feed energy back into the ISM gas where they formed. Two types of energetic feedback are considered in these simulations, supernovae and stellar radiation. Supernova feedback is implemented using the blastwave formalism described in Stinson et al. (2006) and deposit $10^{51}$ erg of energy into the surrounding medium. Since this gas is dense, the energy would be quickly radiated away due to efficient cooling. For this reason, cooling is disabled for particles inside the blast region $R = 10^{10.51} E_{51}^{0.52} n_0^{0.16} P_0^{-0.26}$ pc and for the length of time $t = 10^{0.63} E_{51}^{0.37} n_0^{-0.30} P_0^{-0.25}$ yr given in McKee & Ostriker (1977). Here, $E_{51} = 10^{51}$ erg, $n_0$ is the ambient hydrogen density, and $P_0 = 10^8 P_\text{dyn}$ k$^{-1}$, where $P_0$ is the ambient pressure and $k$ is the Boltzmann constant. Both $n_0$ and $P_0$ are calculated using the SPH kernel for the gas particles surrounding the star.

Metals are ejected from Type II supernovae (SNe II), Type Ia supernovae (SNe Ia) and the stellar winds driven from asymptotic giant branch (AGB) stars. Ejected mass and metals are distributed to the nearest-neighbour gas particles using the smoothing kernel. Details of the manner in which metals are incorporated into the code are found in Stinson et al. (2006). The prescribed SN II and SN Ia yields have been updated in this study. The SN II oxygen and iron use fits to Woosley & Weaver (1995). \( \hat{E} \) For SNe Ia, we use the $W_7$ yields from table 1 of Nomoto et al. (1997). Metal diffusion is also included, such that unresolved turbulent mixing is treated as a shear-dependent diffusion term, as described in Shen et al. (2010). The allows proximate gas particles to mix their metals. Metal cooling is calculated based on the diffused metals.

The effects of stellar radiation have only recently begun to be considered in galaxy simulations (Hopkins, Quataert & Murray 2011). Here, we model the luminosity of stars using the Bressan et al. (1993) mass–luminosity relationship. Typically, this relationship leads to $10^{53}$ erg of energy being released from the high-mass stars over the course of the 0.8 Myr between star formation calculations. These photons do not couple efficiently with the surrounding ISM (Freyer, Hensler & Yorke 2006). We thus do not want to couple all of this energy to the surrounding gas in the simulation. To mimic this highly inefficient energy coupling, we inject 10 per cent of the energy as thermal energy in the surrounding gas, and cooling is not turned off for this form of energy input. It is well established that such thermal energy injection is highly inefficient at the spatial and temporal resolution of the type of cosmological simulations used here (Katz 1992). This is primarily due to the characteristic cooling timescales in the star-forming regions being lower than the step time of the simulations. The dynamical effect of this feedback is negligible, as is the overall coupling of energy to the ISM, but high-mass-star radiation feedback does reduce star formation in the region immediately surrounding a recently formed star particle (full details of this radiative feedback will be presented in a separate paper, Stinson et al. 2011, in preparation).

3 THE SIMULATED GALAXY: PROPERTIES

The simulated galaxy has a total stellar mass of $1.4 \times 10^{10} \, M_\odot$, an H I mass of $1.9 \times 10^{10} \, M_\odot$ and a total gas mass (within $R_\text{vir}$) of $1.5 \times 10^{10} \, M_\odot$. The value log($M(\text{H I})/L_\text{K}$) = −0.8 fits right in the middle of the relation for observed galaxies (Verheijen et al. 2010). The disc has a metallicity which peaks at [Fe/H] = −0.5, while the cold gas has O/H + 12 = 8.25. The simulated galaxy’s merger history is referred to in the analysis which follows. The interaction of the last major merger (mass ratio 2:1) begins at $z \sim 2.7$, with coalescence finished by $z \sim 2.2$ and is followed rapidly by two other significant merger events (mass ratios of 10:1 and 20:1). We identify the period between $z = 2.7$ and $z = 1.7$ as the galaxy’s ‘merger epoch’. Since $z \sim 1.7$, several dark matter merger events occur, but these are too low in mass to contain baryons.

In Fig. 1, we plot the surface brightness profile at $z = 0$ in the SDSS g band, shown face-on and edge-on. The loose spiral arms are indicative of a late-type galaxy. The existence of a bar is also evident, and we contend that the simulated galaxy would be classified as SBc/d. These surface profile maps were created with SUNRISE (Jonsson 2006), which allows us to measure the dust-reprocessed spectral energy distribution (SED) of every resolution element of our simulated galaxies from the far-UV to the far-IR with a full 3D treatment of radiative transfer. We assume a simple relationship between metallicity of gas, which is traced in the simulations, and dust by using a constant dust-to-metal ratio of 0.4 (Dwek 1998). Filters mimicking those on major telescopes are used to create mock observations. SUNRISE uses Monte Carlo techniques to calculate radiation transfer through astronomical dust, including such effects in the determination of SEDs.

The galaxy sits in the blue cloud in the $u - g - M_\text{g}$ colour–magnitude diagram of SDSS galaxies, reproduced from Blanton (2006) in Fig. 2, with the trend lines of the blue and red clouds indicated. The simulated galaxy is shown as star symbols; the light blue star shows the face-on values, while the dark blue stars show various angles of inclination (0\(^\circ\), 30\(^\circ\), 45\(^\circ\), 60\(^\circ\) and 90\(^\circ\)), with greater inclination resulting in redder colours and lower magnitudes. The inclusion of the effects of dust reprocessing explains the significantly lower luminosity and redder colour of the simulation when seen edge-on.

The rotation curve ($V_c = \sqrt{\frac{M(< r)}{r^3/\tau}}$) of the simulation is shown in Fig. 3 at $z = 0$ (blue line), $z = 0.4$ (green) and $z = 1$ (red). Also shown are the contributions from stars (dotted lines) and dark matter (dashed) at these times. The flat curve at $z = 1$ reflects the success of our simulation in preventing excessive star formation in the central regions during the merger epoch. The $z = 0$ curve is not perfectly flat, and perhaps indicates that the secular processes
which build the bulge may be too efficient, and also indicates that, despite significant improvements, our simulations do not yet exactly reproduce the mass distribution of real galaxies.

We plot the observed Tully–Fisher relation in Fig. 4, using data from Pizagno et al. (2007), who plotted the SDSS i-band magnitudes against $V_{80}$, the rotation velocity at the radius which encompasses 80 per cent of the i-band flux (open squares). Our simulated galaxy is overplotted using star symbols, where we show $V_{80}$ (red star) to mimic the observations, as well as $V_{\text{max}}$ (blue star), to show that the degree of the inner peak in our rotation curve is not ‘catastrophic’. Also overplotted as triangles is the recent ‘Eris’ simulation (Guedes et al. 2011), with colours again indicating $V_{80}$ (red triangle) and $V_{\text{max}}$ (blue triangle). Using input physics and resolution similar to our simulation, ‘Eris’ also has a good fit to the Tully–Fisher relation which does not depend on the radius at which the measurement is made.

The SDSS i-band surface brightness maps of the simulation at redshift $z = 1$ (left), $z = 0.4$ (middle) and $z = 0$ (right) are shown in Fig. 5, with the surface brightness range indicated in the colour bar. Note the inside-out growth of the disc and the strong bar is formed by $z = 0.4$. The second mode of the Fourier harmonics of the simulations is shown in Fig. 6, confirming that no bar exists at $z = 1$, but a strong bar with $h_b/h_l \sim 1.2$ is formed by $z = 0.4$ (where $h_b$ is the bar length and $h_l$ is the disc scalelength). The bar weakens somewhat by $z = 0$.

In the three panels of Fig. 7, we show the decompositions of the SDSS i-band surface brightness maps from Fig. 5. Note that all these 1D profile fits were cross-checked using the galfit code (Peng et al. 2010), producing similar results. At $z = 1$ (left panel), the simulation has formed a pure disc galaxy, best fit by a single Sersic profile having Sersic index $n = 1.1$. Recall that this is $\sim 2$ Gyr since the last significant merger event. At $z = 0.4$ (middle panel) and $z = 0$ (right panel), we fit a bulge+bar+disc. Also shown in the panels are the fit parameters, i.e. disc scalelength ($h$) and central surface brightness ($u_0$), and the three Sersic parameters for the bulge and bar, i.e. the effective brightness ($u_e$), effective radius ($r_e$) and Sersic index ($n$). In our decompositions, we derive very low Sersic indices for the bulge component. We caution that this quantity is not reliable, due to gravitational softening which will ‘expand’ the inner mass distribution, with an effect out to $\sim 4$ softening lengths ($\sim 620$ pc in our simulation), which will lower the Sersic index. The amount of light/mass in the derived component should not be affected, so the derived B/T results are reliable ($B/T = 0.0$, $0.12$ and $0.21$ at $z = 1$, $0.4$ and $0$, respectively).

Furthermore, we note that other properties of secularly formed ‘pseudo’-bulges are not definitive (Kormendy & Kennicutt 2004), but more ‘indicative’. So, although our bulge is also flat ($\epsilon_{\text{bulge}}/\epsilon_{\text{disc}}$ ranges between 0.55 and 0.9, depending on viewing angle in

\end{figure}
relation to the bar, where $\epsilon$ is the ellipticity) and is an oblate rotator ($V_{\text{max}}/\sigma_V = 1.4$, $\epsilon_{\text{bulge}} = 0.48-0.75$, again depending on viewing angle), by far the safest evidence that our simulated galaxy’s bulge formed secularly is in the surface brightness profile evolution and its relation to merger events, from which we can determine that the bulge did not form from gas which lost its angular momentum due to interactions during the merger epoch, but rather it formed via secular processes during the life of the disc.

4 REDISTRIBUTING ANGULAR MOMENTUM

In this section, we identify and trace all gas which has lost angular momentum and cooled to the bulge region of the simulated galaxy during the galaxy’s ‘merging epoch’. Specifically, we identify any cold gas ($T < 30000$ K) within 2 kpc of the centre of the galaxy at any time between $z = 2.7$ and $z = 1.7$. This gas generally leads to classical bulge formation. In what follows, we refer to this gas as ‘bulge gas’ (BG). There is $3.0 \times 10^9 M_\odot$ of such BG, which is $\sim 20$ per cent of the mass of stars in the galaxy at $z = 0$. Note that time resolution in our output steps means that it is possible that we miss some of the cold gas which is in the bulge region during the merger epoch, so $3.0 \times 10^9 M_\odot$ is a lower bound. But there is no bias in our selection; the BG that we trace, and from which our conclusions are drawn, is a representative sample of cold gas in the bulge region during the merger epoch.

By $z = 0$, 71 per cent ($2.13 \times 10^9 M_\odot$) of the BG has formed stars. Of the 29 per cent ($8.7 \times 10^8 M_\odot$) remaining as gas at $z = 0$, 14 per cent ($1.2 \times 10^8 M_\odot$) has been blown entirely out of the galaxy, while 11 per cent ($1.0 \times 10^8 M_\odot$) has subsequently cooled down to form $\text{H} I$ and is feeding star formation in the disc. In Fig. 8, we plot the star formation history of all stars in the simulated galaxy at $z = 0$ (black line). The blue line shows all stars formed from BG. Redshifts are included on the upper x-axis. Note the extended star formation history of the stars formed from BG. Although 71 per cent of BG forms stars by $z = 0$, only 9 per cent of it forms stars rapidly after it was first identified as being in the bulge during the merger epoch. The starburst from the 9 per cent BG which forms stars during the merger epoch ejects the remaining 91 per cent of the BG from the bulge region, much of which returns to the galaxy and forms stars at a later time. We note that these large-scale outflows also act to

Figure 4. The Tully–Fisher relation. Open squares, data from Pizagno et al. 2007 using the SDSS $i$ band to measure $V_{80}$; star symbols, our simulated galaxy, using $V_{80}$ (red star) and $V_{\text{max}}$ (blue star); triangles, the recent ‘Eris’ simulation (Guedes et al. 2011), using $V_{80}$ (red triangle) and $V_{\text{max}}$ (blue triangle).

Figure 5. SDSS $i$-band surface brightness maps of the simulation at redshift $z = 1$ (left), $z = 0.4$ (middle) and $z = 0$ (right). The disc grows inside out. A strong bar is formed by $z = 0.4$.

Figure 6. The amplitude of the second Fourier mode of the simulation at redshift $z = 1$ (green), $z = 0.4$ (red) and $z = 0$ (blue). The strong bar formed by $z = 0.4$ is not present at $z = 1$.

Figure 7. Decompositions of the SDSS $i$-band surface brightness maps from Fig. 5. At $z = 1$ (left panel), there is a pure disc galaxy, best fit by a single Sérsic fit having Sérsic index $n = 1.1$. At $z = 0.4$ (middle panel) and $z = 0$ (right panel), we fit a bulge+bar+disc. We caution that the Sérsic indices of the bulge components are not reliable because of gravitational softening. We do not expect that the derived mass associated with each component ($B/T = 0.12$ and 0.21 at $z = 1, 0.4$ and 0, respectively) will be affected by this.

Figure 8. Black line: the star formation history of our simulation; blue line, the formation history of stars which form from the BG, defined as any cold ($T < 30000$ K) gas within 2 kpc of the centre of the galaxy during the merger epoch of the galaxy ($2.7 > z > 1.7$). Twenty per cent of all stars formed from BG. Redshifts are shown on the upper $x$-axis.

prevent gas from falling to the central region during this merger epoch, enhancing their effectiveness at preventing bulge formation.

Fig. 9 shows the angular momentum distribution of BG (red line) when it was identified. The blue line shows the $z = 0$ angular momentum distribution of the stars formed from BG. These two lines are normalized so that the area under the curves indicates the mass. Also shown for perspective (black line) is the angular momentum distribution of observable ‘baryons’ at $z = 0$, where baryons = stars + $\text{H}_1$ gas. The baryons distribution is normalized to have a peak at the same height as the BG. The median (mean) values for BG, stars formed from BG and $z = 0$ baryons are 35.7 (43.9), 92 (205) and 164 (305) km s$^{-1}$ kpc, respectively. The shape of the distribution of stars formed from BG (blue line) closely resembles the $z = 0$ baryon distribution, while the BG (red line) has low angular momentum.

2 kpc with $T < 30000$ K) is plotted against the age of the stars formed from BG. In the middle panel, the maximum distance that BG reaches from the centre of the galaxy subsequent to the time when they were identified is plotted against the age of BG stars. In the bottom panel, the mean angular momentum of BG stars is plotted against their age. Nine per cent of the BG forms stars in the bulge region shortly after it is first identified, before it is blown out of the central region, and consequently forms these stars with the low angular momentum it had when identified (Fig. 9). Supernova feedback heats gas which has low angular momentum and removes it from the inner central region of the galaxy, with the hottest gas travelling the farthest from the centre. The ejected gas mixes with the corona gas, as well as later accreting gas, and returns to the disc with a significantly altered angular momentum distribution. In particular, gas that is re-accreted from the galactic fountain at later times has a significantly less negative and low angular momentum baryons, a far greater amount of high angular momentum material, a higher median angular momentum and forms stars in the disc rather than bulge.

the more massive simulated galaxy considered in this study. Both processes occur at both mass scales in our simulations, with lower than universal baryon fractions indicating that ejection may play a central role at all galaxy mass scales.

We caution that the relative significance of ejection to redistribution is probably not precisely reproduced in current simulations. This is due to the uncertainty involving the inclusion of feedback and the manner in which it couples to the ISM, a problem which is inherent to all galaxy formation models. In a semi-analytic study which assumes the ejection of low angular momentum gas, Dutton & van den Bosch (2009) found that it was necessary to couple 25 per cent of SNe energy to outflows to produce realistic disc galaxy populations. Current estimates of the relationship between stellar mass and halo mass (Mandelbaum et al. 2006; Koposov et al. 2008; Dutton et al. 2010; Guo et al. 2010; Moster et al. 2010; Avila-Reese et al. 2011; More et al. 2011) indicate that the current simulation has a factor \( \sim 2-3 \) too many stars, implying that the role of ejection of low angular momentum gas was most likely underestimated for a galaxy of the mass considered in this study. We note that the key observable for detecting ejection is in fact baryon rather than stellar mass fraction, but the fact that our simulation has a reasonable value of \( \frac{H}{L} \) means that we can assume that we have a similar overabundance of baryons for our halo mass. What we expect is the relative importance of redistribution compared to ejection to increase in more massive disc galaxies, compared to their low-mass counterparts, and that the ejection fraction due to SNe would be the lowest for \( L_* \) galaxies where the ratios of stellar mass (Guo et al. 2010; Moster et al. 2010) and baryonic mass (Bell et al. 2003) to dark halo mass are both at their highest. More massive systems, even groups and clusters of galaxies, also have a baryon fraction that is less than universal (McCarthy, Bower & Balogh 2007; Giodini et al. 2009; Dai et al. 2010), but this is widely attributed to the affects of AGNs which are not included in these simulations.

5.2 Additional central energy sources

Our simulations do not include all possible energy sources, and any extra central heating, for example from black holes, nuclear star clusters (McLaughlin, King & Nayakshin 2006; Rodríguez-González et al. 2011) or a top-heavy initial mass function (IMF) in the bulge (Ballero, Kroupa & Matteucci 2007), would add to the efficacy of our model. We again note that the outflows due to starbursts triggered during merger events actually prevent gas flowing to the central regions, enhancing their effectiveness (it was shown in Paper I that it is preferentially low angular momentum gas above and below the plane that is prevented from being accreted).

5.3 Angular momentum transfer

In a previous study of angular momentum transfer in similar galaxy formation simulations, Roškar et al. (2010) showed that outer disc warps result from torquing of the cold gas by a massive (misaligned) hot gas halo. Due to this torquing in the outer halo, the cold gas aligns with the spin of the hot gas halo by the time it reaches the central region. In those simulations, all the gas (clumpy, shocked, cold flow, recycled from disc) ended up with the same angular momentum distribution, due to this torquing, coupled with hydrodynamical drag. These processes also occur in our simulations.

On the scale of local galactic fountains, significantly higher resolution simulations can be employed than can be achieved in fully cosmological studies such as ours. Hydrodynamical simulations of these local galactic fountains have shown that both drag and
accretion into clouds can efficiently transfer angular momentum between the galactic corona and gas outflows (Fraternali & Binney 2008; Marinacci et al. 2011). Although there are many differences between the temperatures, time-scales and velocities of the interactions of the galactic fountains in those studies and in ours, this is encouraging. Certainly, there is a need for significant theoretical and observational work to constrain the transport of angular momentum between gas with different origins and phases, particularly in the corona where hot halo gas mixes with newly accreted gas and gas blown from the star-forming regions of the galaxy.

We also note that disc viscosity and gas pressure within the disc due to SNe and stellar winds (Valenzuela et al. 2007) may play a role in angular momentum transport, but some angular momentum must be imparted to the gas prior to re-accretion for it to fall at large enough radii to form part of the disc.

6 SUMMARY

We have formed a simulated, late-type disc galaxy which has no classical bulge. The gas which is driven to the bulge region during the merger epoch, and thus has low angular momentum, is blown out by supernova-powered winds which follow the starbursts that are triggered by the mergers. A significant fraction of the blown out gas is re-accreted at later times and forms disc stars. We show that this redistribution of angular momentum via large-scale galactic fountains can lead to the formation of massive disc galaxies which do not have classical bulges. In Paper I, we showed that galactic outflows will result in the ejection of low angular momentum material and hence the formation of bulgeless dwarf galaxies. The processes outlined in Paper I which relate to ejection of gas remain relevant to biases towards low angular momentum outflows from more massive galaxies, whether or not such gas is re-accreted, and the two papers should be read in conjunction.

We have shown that our self-consistent model for the ejection and redistribution of low angular momentum gas, with the latter increasing in significance in higher mass galaxies, can explain the existence of bulgeless disc galaxies that form hierarchically within a cold dark matter universe. Our model has the implicit assumptions that (i) energy from supernova during merger triggered starbursts couples effectively to the ISM and (ii) angular momentum can be transported between ejected gas and newly accreted and hot halo gas. These processes require significant theoretical and observational work to be better constrained, which will provide crucial tests of our model.
